Accepted 10 December 2015

Available online 4 December 2016

The patient was a 37-year-old woman, with a personal history of muscle weakness, pain in lower limbs and a waddling gait with claudication since she had been 18 months old. In a chest radiography carried out for dyspnea, it was incidentally found that she

had generalized demineralization, with thickening of the diaphyseal cortical bone of the long bones (Fig. 1A, arrows). Given these findings, she underwent whole body bone scintigraphy, to determine the extension of the involvement (Fig. 1B, arrows), which

Fig. 1. (A) Anteroposterior chest radiography showing the irregular thickening of the diaphyseal cortical bone of the long bones, especially in both humeri. This bilateral and symmetrical cortical thickening is also evident in the clavicles, greater in the medial area. (B) Whole body bone scintigraphy in anterior and posterior images, showing multiple abnormal uptakes of ^{99m}Tc -diphosphonates with different uptake intensity, in relation to the osteoblastic activity, which is more evident in diaphyseal regions of the long bones and left hip.

revealed large areas with an increase in osteoblastic activity in the diaphysis of the long bones of her upper and lower limbs, as well as involvement of left hip, knees and tarsus, with different degrees of activity. Molecular genetic testing resulted in the definitive diagnosis of Camurati-Engelmann disease. The genetic diagnosis was subsequently reached in 4 first-degree members of her family with a history of pain in lower limbs and proximal muscle weakness.

Camurati-Engelmann disease is an autosomal dominant disease, described for the first time in 1929,¹ characterized by a progressive diaphyseal dysplasia. To date there have been approximately 300 cases reported in the literature, and the clinical course and progression rates are defined as being highly variable. This rare disabling disease is expressed as the thickening of the endosteum and the periosteum of the diaphyseal cortical bone of the long bones, whereas the epiphysis and metaphysis appear to be conserved. In some cases, the skullcap or hips can be affected.^{2,3} Within the clinical variability, we stress the pain in the limbs, the broad-based waddling gait, muscle weakness, clumsiness for precise movements, and its ability to remain underdiagnosed for years. Bone scintigraphy enables the detection of the generalized bone involvement, with extensive areas showing an increase in the osteoblastic activity in up to 74% of the patients studied.⁴ The disease is determined by mutations in the transforming growth factor $\beta 1$ gene (TGF- $\beta 1$), an important stimulator of bone regeneration, located in chromosome 19q13.1-q13.3.^{5,6} With respect to treatment, the symptoms can be managed with corticosteroids, nonsteroidal anti-inflammatory drugs, proton pump inhibitors and rehabilitation programs, when they are tolerated.

Informative Message

Bone scintigraphy is a simple, noninvasive technique that enables the study of the whole body, showing the areas with the greatest involvement in patients with generalized bone disease. The incidental finding of cortical thickening on imaging studies should be examined by an extensive bone scan to improve staging and its classification.
